Abstract. Decentralized content curation is the process through which uploaded posts are ranked and filtered based exclusively on users’ feedback. Platforms such as the blockchain-based Steemit⁶ employ this type of curation while providing monetary incentives to promote the visibility of high quality posts according to the perception of the participants. Despite the wide adoption of the platform very little is known regarding its performance and resilience characteristics. In this work, we provide a formal model for decentralised content curation that identifies salient complexity and game-theoretic measures of performance and resilience to selfish participants. Armed with our model, we provide a first analysis of Steemit identifying the conditions under which the system can be expected to correctly converge to curation while we demonstrate its susceptibility to selfish participant behaviour. We validate our theoretical results with system simulations in various scenarios.

1 Introduction

The modern Internet contains an immense amount of data; a single user can only consume a tiny fraction in a reasonable amount of time. Therefore, any widely used platform that hosts user-generated content (UGC) must employ a content curation mechanism. Content curation can be understood as the set of mechanisms which rank, aggregate and filter relevant information. In recent years, popular news aggregation sites like Reddit⁷ or Hacker News⁸ have established crowdsourced curation as the primary way to filter content for their users. Crowdsourced content curation,

⁷ <https://www.reddit.com/> Accessed: 2018-09-25

⁸ <https://news.ycombinator.com/> Accessed: 2018-09-25

as opposed to more traditional techniques such as expert- or algorithmic-based curation, orders and filters content based on the ratings and feedback of the users themselves, obviating the need for a central moderator by leveraging the “wisdom of the crowd” [1].

The decentralized nature of crowdsourced curation makes it a suitable solution for ranking user-generated content in blockchain-based content hosting systems. The aggregation and filtering of user-generated content emerges as a particularly challenging problem in permissionless blockchains, as any solution that requires a concrete moderator implies that there exists a privileged party, which is incompatible with a permissionless blockchain. Moreover, public blockchains are easy targets for Sybil attacks, as any user can create new accounts at any time for a marginal cost. Therefore, on-chain mechanisms to resist the effect of Sybil users are necessary for a healthy and well-functioning platform; traditional counter-Sybil mechanisms [2] are much harder to apply in the case of blockchains due to the decentralized nature of the latter. The functions performed by moderators in traditional content platforms need to be replaced by incentive mechanisms that ensure self-regulation. Having the impact of a vote depend on the number of coins the voter holds is an intuitively appealing strategy to achieve a proper alignment of incentives for users in decentralized content platforms; specifically, it can render Sybil attacks impossible.

However, the correct design of such systems is still an unsolved problem. Blockchains have created a new economic paradigm where users are at the same time equity holders in the system, and leveraging this property in a robust manner constitutes an interesting challenge. A variety of projects have designed decentralized content curation systems [3,4,5]. However, a deep understanding of the properties of such systems is still lacking. Among them, Steemit has the longest track record, having been in operation since 2016 and attaining a user base of more than 1.08M⁹ registered accounts¹⁰. Steemit is a social media platform which lets users earn money (in the form of the STEEM cryptocurrency) when creating and curating content in the network. Steemit is the front-end of the social network, a graphical web interface which allows users to see the content of the platform. However, all the backend information is retrieved from a distributed ledger, the Steem blockchain. Steem can be understood as an

⁹ <https://steemdb.com/accounts> Accessed: 2018-09-25

¹⁰ The number of accounts should not be understood as the number of active users, as one user can create multiple accounts.

“app-chain”, a blockchain with a specific application purpose: serving as a distributed database for social media applications [4].

In this work we initiate a study of the foundations of decentralised content curation. We develop a theoretical model of a post-voting system which aims to sort the posts created by users in a distributed and crowd-sourced manner. Our model is constituted by N players who contribute votes in a round-based curation process. The impact of each vote depends on the number of coins held by the player. The posts are arranged in a list, sorted by the value of votes received, resembling the front-page model of Reddit or Hacker News. In the model, players vote according to their subjective opinion on the quality of the posts and have a limited attention span attSpan . Following previous related work, we represent each player’s opinion on each post (i.e. likability) with a numerical value $n \in [0, 1]$ [6,1]. The objective quality of a post will be calculated as the simple summation of all players’ likabilities for the post in question. To measure the properties of such a post-voting system, we say that the system *t-converges* if the t first articles are ordered according to the objective quality of the posts at the end of the execution. After defining and formalizing an abstract post-voting system, we particularize it to model Steemit. We prove the conditions under which Steemit *t-converges* and then we develop a simulation to help us parametrize Steemit according to our post-voting model. Our analysis of the post-voting system of Steemit aims to provide a useful framework to aid the design of future decentralized curation platforms. [Aggelos: This needs more work]

Our Contributions.

- Original treatment following cryptography and simulation-based techniques to model crowdsourced content curation, in opposition to previous academic work which have leaned more towards an analytical and game-theoretic approach.
- Taking in account of subjective likeabilities, the effect of rounds and an agnostic likeability distribution treatment.
- Measurement of the influence of coin-holding (wealth-distribution) in the effectivity of post sorting. New paradigm present in blockchain based systems (main difference with Reddit-like platforms.)
- Proof that Steem does not *t-converge* with the parameters currently used in their implementation. Insights to improve the curation quality of the trending section of steem.
- (Maybe)Impact of the curation quality when greedy players are present in the system.

2 Related Work

User-generated content (UGC) has been identified as a fundamental component of social media platforms and Web 2.0 in general [7]. The content created by users needs to be curated, and crowdsourced content curation [1] has emerged as an alternative to expert-based- [8] or algorithmic-based [9] curation techniques. Motivated by the widespread adoption of crowdsourced aggregation sites such as Reddit or Digg¹¹, several research efforts [10,6] have aimed to model the mechanics and incentives for users in UGC platforms. This surge of interest is accompanied by empirical studies which have shown how social media users behave strategically when they publish and consume content [11]. As an example, in the case of Reddit, users try to maximize their ‘karma’ [12], the social badge of the social media platform [13]. Previous works have analyzed content curation from an incentives and game-theoretic standpoint [6,10,14,11]. Our formalisation is based on these models and inherits features such as the quality distribution of the articles and the user’s attention span [1,6]. In terms of measuring our results, our analysis of *t-convergence* is similar to the top-*k* posts in [1]. We also compare our *t-convergence* metric with the rank correlation coefficients Kendall’s Tau [15] and Spearman’s Rho [16] to measure content curation efficiency.

Our approach describes the mechanics of post-voting systems from a computational perspective drawing inspiration from the real-ideal world paradigm of Cryptography [17,18] in the definition of convergence. [Aggelos: I removed the Arrow theorem reference - see below] Post-voting systems are closely tied to voting mechanisms, as studied within social choice [19,20,21]. The study of voting rules has focused on the analysis of communication complexity and the accuracy of results when a single winner must be chosen. In contrast, we do not seek to investigate the election of one winner but analyze the curation quality of the entire list of items. Even though we share an iterative (i.e. rounds based) voting scheme with some of these works [22], we remark that our crowdsourced curation model has fundamentally different goals from election-like schemes of previous literature, making the two largely incomparable. [Aggelos: on what grounds is this substantiated? I don’t see from where it follows. In general this whole paragraph has problems; we cannot say that our point of difference is that we analyse the whole list and election systems seek to find a single winner; there many election systems that do elect a committee, MPs etc. Be very careful here. Moreover cardinal voting should be mentioned as

¹¹ <http://digg.com/> Accessed: 2018-09-25

well as Gibbard’s theorem, showing that content curation can be subject to strategic behaviour of participants.]

Content curation is also related to the concept of online governance. The governance of online communities such as Wikipedia has been thoroughly studied in previous academic work [23,24]. However, the financially incentivized governance processes in blockchain systems, where the voters are at the same time equity-holders, have still many open research questions [25,26]. This shared ownership property has triggered an interest to build UGC social media platforms backed by distributed ledgers, in which users can be rewarded for the content they create and variants of coin-holder voting are used to decide how this rewards are distributed. The effects on the quality of content for establishing explicit financial incentives for content creators and curators in Steemit has been analyzed in [27]. However, this work focuses on analyzing the content of the posts created in Steemit and does not aim to understand the dynamics behind the platform. Beyond the Steemit’s whitepaper [4], the series of blog posts [28,29] effectively extend the economic analysis in Steem. In parallel with Steemit, other projects such as Synereo[3] and Akasha¹² are exploring the convergence of social media and decentralized content curation. Beyond blockchain-based social media platforms, coin-holder voting systems are present in decentralized platforms such as DAOs [30] and in different blockchain protocols [31,32]. However, most of these systems use coin-holder voting processes to agree on a value or take a consensual decision.

3 Model

3.1 Notation

- We denote an ordered list of elements with $A = [e_1, \dots, e_n]$ and the i -th element of the list with $A[i] = e_i$.
- Let $n \in \mathbb{N}^*$. $[n]$ denotes $\{1, 2, \dots, n\}$.

3.2 Post list

Definition 1 (Post). Let $N \in \mathbb{N}^*$. A post is defined as $p = (i, l)$, with $i \in [N], l \in [0, 1]^N$.

- **Author.** The first element of a post is the id of its creator, i .
- **Likeability.** The likeability of a post is defined as $l \in [0, 1]^N$.

¹² <https://akasha.world/Accessed:2018-09-25>

Definition 2 (Ideal Score of a post). Let post $p = (m, l)$. We define the ideal score of p as $\text{idealSc}(p) = \sum_{i=1}^{|l|} l_i$.

The ideal score of a post is a single number that represents its overall worth to the community. By using simple summation, we assume that the opinions of all players have the same weight.

Definition 3 (Post List). Let $M \in \mathbb{N}^*$. A post list $\mathcal{P} = [p_1, \dots, p_M]$ is an ordered list containing posts. It may be the case that two posts are identical.

In an ordered list of posts where higher posts are more visible, the “common interest” would require that a post with higher ideal score appear before another post with a lower score.

Definition 4 (t -Ideal Post Order). Let \mathcal{P} a list of posts, $t \in \mathbb{N}^*$. We say that \mathcal{P} is in t -ideal order and that the property $\text{IDEAL}^t(\mathcal{P})$ holds if

$$\forall i < j \in t, \text{idealSc}(\mathcal{P}[i]) \geq \text{idealSc}(\mathcal{P}[j]) \quad .$$

3.3 Post Voting System

A post voting system has the objective to arrange the posts according to the preferences of the participants. The ideal order is defined based on the likeability matrix for the posts.

Definition 5 (Post-Voting System). Consider four PPT algorithms INIT , AUX , HANDLEVOTE and VOTE . The tuple \mathcal{S} consisting of the four algorithms is a Post-Voting System. \mathcal{S} parametrizes the following two ITMs:

$\mathcal{G}_{\text{Feed}}$ is a global functionality that accepts two messages: **read**, which responds with the current list of posts and **vote**, which can take various arguments and does whatever is defined in HANDLEVOTE .

Π_{honest} is a protocol that sends **read** and **vote** messages to $\mathcal{G}_{\text{Feed}}$ whenever it receives (**activate**) from \mathcal{E} .

Algorithm 1 $\mathcal{G}_{\text{Feed}}(\text{INIT}, \text{AUX}, \text{HANDLEVOTE})(\mathcal{P}, \text{initArgs})$

```
1: Initialization:
2:    $\mathcal{U} \leftarrow \emptyset$  ▷ Set of players
3:    $\text{INIT}(\text{initArgs})$ 
4:
5: Upon receiving (read) from  $u_{\text{pid}}$ :
6:    $\mathcal{U} \leftarrow \mathcal{U} \cup \{u_{\text{pid}}\}$ 
7:    $\text{aux} \leftarrow \text{AUX}(u_{\text{pid}})$ 
8:   Send (posts,  $\mathcal{P}$ ,  $\text{aux}$ ) to  $u_{\text{pid}}$ 
9:
10: Upon receiving (vote,  $\text{ballot}$ ) from  $u_{\text{pid}}$ :
11:    $\text{HANDLEVOTE}(\text{ballot})$ 
```

Algorithm 2 $\Pi_{\text{honest}}(\text{VOTE})$

```
1: Upon receiving (activate) from  $\mathcal{E}$ :
2:   Send (read) to  $\mathcal{G}_{\text{Feed}}$ 
3:   Wait for response (posts,  $\mathcal{P}$ ,  $\text{aux}$ )
4:    $\text{ballot} \leftarrow \text{VOTE}(\mathcal{P}, \text{aux})$ 
5:   Send (vote,  $\text{ballot}$ ) to  $\mathcal{G}_{\text{Feed}}$ 
```

Definition 6 (Post-Voting System Activation Message). We define act_{pid} as the message (**activate**, pid), sent to u_{pid} .

Definition 7 (Execution Pattern). Let $N, R \in \mathbb{N}^*, N \geq 2$.

$$\text{ExecPat}_{N,R} = \{(\text{act}_{\text{pid}_1}, \dots, \text{act}_{\text{pid}_{NR}}) : \\ \forall i \in [R], \forall k \in [N], \exists j \in [N] : \text{pid}_{(i-1)N+j} = k\} ,$$

*i.e. activation messages are grouped in R rounds and within each round each player is **activated** exactly once. The order of activations is not fixed.*

Let Environment \mathcal{E} that sends messages $\text{msgs} = (\text{act}_{\text{pid}_1}, \dots, \text{act}_{\text{pid}_n})$ sequentially. We say that \mathcal{E} respects $\text{ExecPat}_{N,R}$ if $\text{msgs} \in \text{ExecPat}_{N,R}$. (Note: this implies that $n = NR$.)

Definition 8 ((N, R, M, t) -convergence under honesty). We say that a post-voting system $\mathcal{S} = (\text{INIT}, \text{AUX}, \text{HANDLEVOTE}, \text{VOTE})(N, R, M, t)$ -converges under honesty (or t -converges under honesty for N players, R rounds and M posts) if, for every input \mathcal{P} such that $|\mathcal{P}| = M$, for every

\mathcal{E} that respects $\text{ExecPat}_{N,R}$ and given that all protocols execute Π_{honest} , it holds that after \mathcal{E} completes its execution pattern, $\mathcal{G}_{\text{Feed}}$ contains a post list \mathcal{P} such that $\text{IDEAL}^t(\mathcal{P})$ is true.

Definition 9 (Steem system). The Steem system is the post voting system \mathcal{S} with parameters $a, b, \text{regen} \in [0, 1] : a + b < 1, \left\lceil \frac{a+b}{\text{regen}} \right\rceil > 1, \text{attSpan} \in \mathbb{N}^*$. The parametrizing procedures can be found in Appendix B.

Remark 1. The constraint $a + b < 1$ ensures that a single vote of full weight cast by a player with full voting power does not completely deplete her voting power. The constraint $\left\lceil \frac{a+b}{\text{regen}} \right\rceil > 1$ excludes the degenerate case in which the regeneration of a single round is enough to fully replenish the voting power in all cases; in this case the purpose of voting power would be defeated.

Remark 2. The Steem blockchain protocol defines $a = 0.02, b = 0.0001$ and $\text{regen} = \frac{3}{5 \cdot 24 \cdot 60 \cdot 60} = 0.00000694$, thus $\left\lceil \frac{a+b}{\text{regen}} \right\rceil = 2895$.

Remark 3. We omit Steem Power, the Steem platform currency, from our analysis.

Theorem 1. The Steem system (N, R, M, M) -converges if and only if SP is constant and $R - 1 \geq (M - 1) \left\lceil \frac{a+b}{\text{regen}} \right\rceil$.

Proof Sketch. When $R - 1 \geq (M - 1) \left\lceil \frac{a+b}{\text{regen}} \right\rceil$, there are enough rounds to ensure full regeneration of every player's voting power between two votes and thus the resulting post list reflects the true preferences of the players. In the opposite case, we can always craft a post list that exploits the fact that some votes are cast with reduced voting power in order to trick the system into placing a wrong post in the top position. \square

The above result is tight. If the conditions are violated the above theorem is not true. See Appendix A for full proof.

4 Simulation

4.1 Introduction

In the previous section, we analyzed and proved the convergence bounds on the number of rounds in which Steemit retrieves optimal results in

the curation of content. We measure the quality of curation of the platform with our *t-convergence* metric, which identifies if the t-top posts in the final lists of posts are equal to the t-posts list on the ideal quality order. The outcomes obtained in our theoretical analysis of the platform have motivated us to better understand the implications of these results in practice. In the current section, we create a simulation framework to replicate the execution of Steemit’s post-voting system, based on the protocols of section(x) and Appendix.

In particular we will consider two scenarios for our simulation: when all users are honest (i.e. vote according to the likability distribution) as in section X and when users behave selfishly in order to improve the final position of their posts. With the first scenario, we aim to understand in more depth the practical implementation of the bounds obtained in the previous section. We study how the curation quality of the system varies with the number of voting rounds to give a better grasp on the curation properties a post-voting system can achieve when the number of available rounds is tight. The second case tries to measure how resilient is the curation quality of Steemit to malicious agents. We study which are the effects of a subset of users of the platform not following the likability distribution of the posts to cast votes and voting to maximize the popularity of their own posts.

Modeling greedy behavior. Steem allows its users to self-vote. Self-voting occurs when a user upvotes their own content. While this cannot be regarded as an intrinsic flaw in the protocol, if self-voting abusively is profitable, there are no incentives for rational players to follow the curation system defined in our model by the Likability distribution.

In Steem, users cannot vote more than once for the same piece of content, so greedy users can create dummy posts and constantly vote for them. In our model of section X, we establish the condition that users can create only one post at the beginning of the voting execution (see algo.). Therefore, to replicate the effects of abusively self-voting, we introduce *hub-and-spoke* voting rings, where a greedy user create a defined number sybil accounts which will vote for the post created by the selfish player.

4.2 Methodology

To measure the curation quality we employ the *t-convergence* used in section X. However, our analysis now aims to capture how this metric varies depending on the system parameters not in the calculation of a

bound for the curation success. The evolution of the *t-convergence* on the list of posts for different number of rounds will provide a better intuition of these research questions. To complement the convergence analysis for the top-t posts of the list, we use two statistical coefficients, Kendall’s Tau and Spearman’s Rho, to measure the correlation of the curated list and the ideal list of posts based on the likability distribution.

Rank correlation coefficients. To quantify the similarity between two ordered list of posts we employ Spearman’s Rho and Kendall’s Tau, two of the most popular rank correlation coefficients [15]. When measuring rank correlation, these coefficients will measure the statistical significance between two lists, retrieving a value $\rho, \tau \in [-1, 1]$. When the ranking of two lists is completely unrelated to each other, the rank correlation coefficient will be 0. If there exists rank correlation, the coefficients oscillate between 1 and -1 , meaning absolute correlation (i.e. the ranks of the lists are equal) and absolute inverse correlation (i.e. the lists are ranked in reversed order).

Spearman’s Rho. (maybe) Description and Formula

Kendall’s Tau. (maybe) Description and Formula

In addition to *t-convergence* and the rank correlation coefficients used in the “all-honest” scenario, we include a *selfish-rewards* metric to quantify how successful for the selfish players was deviating from the protocol. In particular, we compare the position of the post created by a selfish (or greedy, dunno what’s better) user with the ranking of the post following the ideal order of qualities. In this way, we are able to measure how advantageous is for users to behave greedily and how this behavior affects the overall quality of curation of the platform (i.e. using the rest of curation quality metrics previously defined).

4.3 Results

Scenario A: All users are honest The simulation scenario in which all users follow the established protocol is an extension of the t-convergence bounds obtained in the previous section and permits us study the curation problem from a more practical perspective.

Scenario B: Selfish users The inclusion of selfish actors in our simulation of Steemit permits us measuring the system’s resilience to deviations

of the expected curation protocol (i.e. all users voting according to their likability). As previously mentioned, we constitute voting rings in which one user, the ring leader, creates a number of sybil accounts which will vote firstly for the post of the ring leader. In order to understand how the presence of voting rings affect the quality of curation of the platform, we run our simulations varying key parameters such as the ring size or the ration between greedy participants and the total number of users. From our analysis in Scenario A, we are able to run the simulation in the most relevant curation conditions, such as bounding number of rounds when the *t-convergence* is reached.

5 Results

Steem won't achieve high quality posts.

6 Further Work

Posts at any time

7 Conclusion

Keep inventing new decentralized content curation platforms.

8 Acknowledgements

We thank Edith Elkind, Professor at the University of Oxford, for her insightful comments and guidance on relevant previous academic work. We also want to acknowledge the help and recommendations from Kousha Etesami, Professor at the University of Edinburgh, in order to prove the convergence bound of Steem.

We would also like to extend our gratitude to Steemit's blogger @jga, Julián González. His posts [28,29] analyzing Steem internals which successfully complement Steemit's Whitepaper [4] have been of invaluable help for our understanding of the system.

Appendix A Proof of Theorem 1: Steem convergence

Proof. – (\Leftarrow) Suppose that

$$R - 1 \geq (M - 1) \left\lceil \frac{a + b}{\text{regen}} \right\rceil . \quad (1)$$

Let $\text{pid} \in [N]$. In this case it is $R \geq M$ and according to **VOTETHIS-ROUND** in Algorithm 6, u_{pid} votes non-null in rounds (r_1, \dots, r_M) with $r_i = \left\lfloor (i-1) \frac{R-1}{M-1} \right\rfloor + 1$. Observe that:

$$(1) \Rightarrow \frac{R-1}{M-1} \geq \left\lfloor \frac{a+b}{\text{regen}} \right\rfloor \xrightarrow[\text{integer}]{\text{rhs}} \left\lfloor \frac{R-1}{M-1} \right\rfloor \geq \left\lfloor \frac{a+b}{\text{regen}} \right\rfloor, \quad (2)$$

$$\forall i \in [M] \setminus \{1\}, r_i \in \left\{ r_{i-1} + \left\lfloor \frac{R-1}{M-1} \right\rfloor, r_{i-1} + \left\lceil \frac{R-1}{M-1} \right\rceil \right\}. \quad (3)$$

From (2) and (3) we have that $\forall i \in [M-1], r_{i+1} - r_i \geq \left\lceil \frac{a+b}{\text{regen}} \right\rceil$. We will now prove by induction that $\forall i \in [M], \mathbf{VP}_{\text{pid}, r_i} = 1$.

- For $i = 1$, $\mathbf{VP}_{\text{pid}, 1} = 1$ (Algorithm 3, line 4).
- Let $\mathbf{VP}_{\text{pid}, r_i} = 1$. Until r_{i+1} , a single non-null vote is cast by u_{pid} , which reduces \mathbf{VP}_{pid} by at most $a+b$ (Algorithm 5, line 7) and at least $\left\lceil \frac{a+b}{\text{regen}} \right\rceil$ regenerations, each of which replenishes \mathbf{VP}_{pid} by regen . Thus

$$\mathbf{VP}_{\text{pid}, r_{i+1}} \geq \min \left\{ \mathbf{VP}_{\text{pid}, r_i} - a - b + \text{regen} \left\lceil \frac{a+b}{\text{regen}} \right\rceil, 1 \right\} \geq 1.$$

But \mathbf{VP}_{pid} cannot exceed 1 (line 4), thus $\mathbf{VP}_{\text{pid}, r_{i+1}} = 1$.

Since the above holds for every $\text{pid} \in [N]$, it holds that at the end of the execution, all votes have been cast with full voting power, thus $\forall i \in [M], \text{sc}_R(\mathcal{P}[i]) = Nb + a \sum_{\text{pid}=1}^N \mathcal{P}[i]_{\text{pid}}$ and the posts in \mathcal{P}_R are sorted by decreasing score (Algorithm 5, line 20). We observe that

$$\begin{aligned} \forall i \neq j \in [M], \text{idealSc}(\mathcal{P}[i]) > \text{idealSc}(\mathcal{P}[j]) &\Rightarrow \\ \sum_{\text{pid}=1}^N \mathcal{P}[i]_{\text{pid}} > \sum_{\text{pid}=1}^N \mathcal{P}[j]_{\text{pid}} &\Rightarrow \\ Nb + a \sum_{\text{pid}=1}^N \mathcal{P}[i]_{\text{pid}} > Nb + a \sum_{\text{pid}=1}^N \mathcal{P}[j]_{\text{pid}}. \end{aligned}$$

Thus all posts will be ordered according to their ideal scores; put otherwise, $\text{IDEALSCORE}^M(\mathcal{P}_R)$ holds.

– (\Rightarrow) Suppose that

$$R-1 < (M-1) \left\lceil \frac{a+b}{\text{regen}} \right\rceil. \quad (4)$$

Several lists of posts will be defined in the rest of the proof. Given that, when all players are honest, the creator of a post is irrelevant, we omit the creator from the definition of posts to facilitate the exposition. Thus every post will be defined as a tuple of likabilities. First, we consider the case when

$$\text{attSpan} + R \leq M . \quad (5)$$

In this case, no player can ever vote for the last post, as we will show now. First of all, (5) $\Rightarrow R < M$, thus all players cast R votes in total. Let $\text{pid} \in N, i \in [R]$ and $v_{\text{pid},i}$ the index of the last post that has ever been in u_{pid} 's attention span until the end of round i , according to the ordering of \mathcal{P} . It is $v_{\text{pid},1} = \text{attSpan}$ and $\forall i \in [R] \setminus \{1\}, v_{\text{pid},i} = v_{\text{pid},i-1} + 1$, since in every round u_{pid} votes for a single post and the first unvoted post of the list is added to their attention span. Note that, since this mechanism is the same for all players, the same unvoted post is added to all players' attention span at every round. Thus $\forall \text{pid} \in N, v_{\text{pid},R} = \text{attSpan} + R - 1 \stackrel{(5)}{<} M$. We deduce that no player has ever the chance to vote for the last post.

The above observation naturally leads us to the following counterexample: Let

$$\begin{aligned} \text{strongPost} &= \left(\underbrace{1, \dots, 1}_N \right) \\ \text{nullPost} &= \left(\underbrace{0, \dots, 0}_N \right) \\ \mathcal{P} &= \left[\underbrace{\text{nullPost}, \dots, \text{nullPost}}_{M-1}, \text{strongPost} \right] \end{aligned}$$

$\forall i \in [M-1]$, it is $\text{idealSc}(\mathcal{P}[M]) > \text{idealSc}(\mathcal{P}[i])$, thus $\forall \mathcal{P}'$ that contain the same posts as \mathcal{P} and $\text{IDEAL}^1(\mathcal{P}')$ holds, it is $\mathcal{P}'[1] = \mathcal{P}[M]$. However, since the last post is not voted by any player and the first post is voted by at least one player, it is $\text{sc}_R(\mathcal{P}[1]) > \text{sc}_R(\mathcal{P}[M])$, thus $\text{IDEAL}^1(\mathcal{P}_R)$ does not hold.

We now move on to the case when $\text{attSpan} + R > M$. Let $V = \min\{R, M\}$. Each player casts exactly V votes. Consider $\mathcal{P}^1 = 1^{M \times N}$ and $\text{pid} \in [N]$. Let

$$i \in [V] : \left(\mathbf{VPreg}_{\text{pid}, r_i} < 1 \wedge \nexists i' < i : \mathbf{VPreg}_{\text{pid}, r_{i'}} < 1 \right) ,$$

i.e. i is the first round in which u_{pid} votes with less than full voting power. Such a round exists in every case as we will show now. Note that, since the first round is a voting round and the voting power of all players is full at the beginning, if i exists it is $i \geq 2$.

- If $R \geq M$, it is $V = M$.

If $\nexists i \in [M] : (\mathbf{VPreg}_{\text{pid}, r_i} < 1 \wedge \nexists i' < i : \mathbf{VPreg}_{\text{pid}, r_{i'}} < 1)$, then $\forall i \in [M], \mathbf{VPreg}_{\text{pid}, r_i} = 1 \Rightarrow \forall i \in [M] \setminus \{1\}, r_i \geq r_{i-1} + \left\lceil \frac{a+b}{\text{regen}} \right\rceil$ to have enough rounds to replenish the voting power after a full-weight, full-voting power vote. Thus $r_M \geq 1 + (M-1) \left\lceil \frac{a+b}{\text{regen}} \right\rceil > R$, contradiction.

- If $R < M$, every player votes on all rounds, thus $r_2 = 2$. Note that

$$\left\lceil \frac{a+b}{\text{regen}} \right\rceil \geq 2 \Rightarrow \frac{a+b}{\text{regen}} > 1 \Rightarrow a+b > \text{regen} . \quad (6)$$

Thus $\forall \text{pid} \in [N], \mathbf{VPreg}_{\text{pid}, r_2} = 1 - a - b + \text{regen} \stackrel{(6)}{<} 0$, thus $i = 2$. We proved that i exists. Since all players follow the same voting pattern, the voting power of all players in each round is the same. Let $\text{rVP} = \mathbf{VPreg}_{1, r_i}$. Assume that $\text{attSpan} < i \vee i > 2$. We cover the case where $\text{attSpan} \geq i \wedge i = 2$ later. In case N is even, let $0 < \gamma < 0, 0 < \epsilon < \gamma(1 - \text{rVP})$,

$$\begin{aligned} \text{weakPost} &= \left(\underbrace{1, \dots, 1}_{N/2}, \underbrace{\gamma - \epsilon, \dots, \gamma - \epsilon}_{N/2} \right) , \\ \text{strongPost} &= \left(\underbrace{\gamma, \dots, \gamma}_{N/2}, \underbrace{1, \dots, 1}_{N/2} \right) , \\ \text{nullPost} &= \left(\underbrace{0, \dots, 0}_N \right) , \\ \mathcal{P} &= \left[\underbrace{\text{weakPost}, \dots, \text{weakPost}}_{i-1}, \text{strongPost}, \underbrace{\text{nullPost}, \dots, \text{nullPost}}_{M-i} \right] . \end{aligned}$$

First of all, it is

$$\begin{aligned} \forall j \in [i-1], \text{idealSc}(\mathcal{P}[j]) &= \frac{N}{2} (1 + \gamma - \epsilon) < \\ &< \frac{N}{2} (1 + \gamma) = \text{idealSc}(\mathcal{P}[i]) \end{aligned}$$

and $\forall j \in \{i + 1, \dots, M\}, \text{idealSc}(\mathcal{P}[j]) = 0 < \text{idealSc}(\mathcal{P}[i])$, thus the strong post has strictly the highest ideal score of all posts and as a result, $\forall \mathcal{P}'$ that contains the same posts as \mathcal{P} and $\text{IDEAL}^1(\mathcal{P}')$ holds, it is $\mathcal{P}'[1] = \mathcal{P}[i]$.

We observe that all players like both weak and strong posts more than null posts, thus no player will vote for a null post unless her attention span contains only null posts. This can happen in two cases: First, if the player has not yet voted for all non-null posts, but the first attSpan posts of the list, excluding already voted posts, are null posts. Second, if the player has already voted for all non-null posts. For a null post to rank higher than a non-null one, it must be true that there exists one player that has cast the first vote for the null post. However, since the null posts are initially at the bottom of the list and it is impossible for a post to improve its ranking before it is voted, we deduce that this first vote can be cast only after the voter has voted for all non-null posts. We deduce that all players vote for all non-null posts before voting for any null post.

We will now see that the first $\frac{N}{2}$ players vote first for all weak posts and then for the strong post. These players like the weak posts more than the strong post. As we saw, they will not vote any null post before voting for all non-null ones. If $\text{attSpan} > 1$ they vote for the strong post only when all other posts in their attention span are null ones and thus they will have voted for all weak posts already. If $\text{attSpan} = 1$ and since no post can increase its position before being voted, the strong post will become “visible” for all players only once they have voted for all weak posts. Thus in both cases the first $\frac{N}{2}$ players vote for the strong post only after they have voted for all weak posts first. The two previous results combined prove that the first $\frac{N}{2}$ players vote for the strong post in round r_i exactly. We also observe that these players have experienced the exact same voting power reduction and regeneration as in the case of \mathcal{P}^1 since they voted only for posts with likeability 1, thus in round r_i their voting power after regeneration is exactly the same as in the case of \mathcal{P}^1 : $\forall \text{pid} \in \left[\frac{N}{2}\right], \mathbf{VP}_{\text{regpid}, r_i} = \text{rVP}$.

We observe that the first $\frac{N}{2}$ players vote for all weak posts with full voting power. As for the last $\frac{N}{2}$ players, we observe that, if $\text{attSpan} < i$, they all vote for the first weak post of the list in the first round, and thus with full voting power. If $\text{attSpan} \geq i$ and $i > 2$, they vote for the strong post in the first round and for the first weak post in r_2 with full voting power. Thus in all cases the last $\frac{N}{2}$ players vote

for the first weak post with full voting power. Therefore, the score of the first weak post at the end of the execution is $\text{sc}_R(\mathcal{P}[1]) = \frac{N}{2}(a+b) + \frac{N}{2}((\gamma - \epsilon)a + b)$.

On the other hand, at the end of the execution the strong post has been voted by the first $\frac{N}{2}$ players with rVP voting power and by the last $\frac{N}{2}$ players with at most full voting power, thus its final score will be at most $\text{sc}_R(\mathcal{P}[i]) \leq \frac{N}{2}(\text{rVP} \cdot \gamma a + b) + \frac{N}{2}(a + b)$. It is

$$\begin{aligned} \epsilon < \gamma(1 - \text{rVP}) &\Rightarrow \\ \frac{N}{2}(\text{rVP} \cdot \gamma a + b) + \frac{N}{2}(a + b) &< \frac{N}{2}(a + b) + \frac{N}{2}((\gamma - \epsilon)a + b) \Rightarrow \\ \text{sc}_R(\mathcal{P}[i]) &< \text{sc}_R(\mathcal{P}[1]) \quad . \end{aligned}$$

Thus $\mathcal{P}_R[1] \neq \mathcal{P}[i]$ and $\text{Ideal}^1(\mathcal{P}_R)$ does not hold.

As for the case when N is odd, let $0 < \epsilon < \gamma \frac{N-3}{N-1}(1 - \text{rVP})$. In this case, we assume that the likeability of the first i posts (weak and strong) for the last player is γ , whereas the likeability of the last $M - i$ posts (the null posts) is 0. This means that the last player votes first for the weak and strong posts and then for the null posts. The rest of the likabilities remain as in the case when N is even. We observe that the ideal score of the strong post is still strictly higher than the rest. Furthermore, since the last player votes for the first weak post within the first i voting rounds, her voting power at the time of this vote will be at least rVP. We thus have the following bounds for the scores:

$$\begin{aligned} \text{sc}_R(\mathcal{P}[i]) &\leq \frac{N-1}{2}(\text{rVP} \cdot \gamma a + b) + \frac{N-1}{2}(a + b) + \gamma a + b \quad , \\ \text{sc}_R(\mathcal{P}[1]) &\geq \frac{N-1}{2}(a + b) + \frac{N-1}{2}((\gamma - \epsilon)a + b) + \text{rVP} \cdot \gamma a + b \quad . \end{aligned}$$

Given the bounds of ϵ , it is $\text{sc}_R(\mathcal{P}[i]) < \text{sc}_R(\mathcal{P}[1])$, thus $\text{Ideal}^1(\mathcal{P}_R)$ does not hold.

We finally cover the previously untreated edge case where $\text{attSpan} \geq i \wedge i = 2$. rVP is defined like before. We first consider the case when N is even and greater than 2: $\exists k \in \mathbb{N} \setminus \{0, 1\} : N = 2k$. Let $0 < \gamma <$

$$1, 0 < \epsilon < 2\gamma \frac{1-\text{rVP}}{(k-1)\text{rVP}},$$

$$\begin{aligned} \text{weakPost} &= \left(\underbrace{1, \dots, 1}_{k-1}, \underbrace{\gamma - \epsilon, \dots, \gamma - \epsilon}_{k-1}, \gamma, \gamma \right), \\ \text{strongPost} &= \left(\underbrace{\gamma, \dots, \gamma}_{k-1}, \underbrace{1, \dots, 1}_{k-1}, \gamma, \gamma \right), \\ \mathcal{P} &= \left[\text{weakPost}, \text{strongPost}, \underbrace{\text{nullPost}, \dots, \text{nullPost}}_{M-2} \right]. \end{aligned}$$

We first observe that

$$\begin{aligned} \forall j \in \{3, \dots, M\}, \text{idealSc}(\mathcal{P}[j]) &= 0 < \\ < \text{idealSc}(\mathcal{P}[1]) = k-1 + (k-1)(\gamma - \epsilon) + 2\gamma = \\ &= k-1 + (k+1)\gamma - (k-1)\epsilon < \\ < k-1 + (k+1)\gamma = \text{idealSc}(\mathcal{P}[2]) \quad , \end{aligned}$$

thus the strong post has strictly the highest ideal score of all posts and as a result, $\forall \mathcal{P}'$ that contains the same posts as \mathcal{P} and $\text{IDEAL}^1(\mathcal{P}')$ holds, it is $\mathcal{P}'[1] = \mathcal{P}[2]$.

The first $k-1$ and the last two players vote first for $\mathcal{P}[1]$ and then for $\mathcal{P}[2]$, whereas players $k, \dots, 2k-2$ vote first for $\mathcal{P}[2]$ and then for $\mathcal{P}[1]$, thus at the end of the execution,

$$\begin{aligned} \text{sc}_R(\mathcal{P}[1]) &= (k-1)(a+b) + 2(\gamma a + b) + (k-1)((\gamma - \epsilon)\text{rVP}a + b) \quad , \\ \text{sc}_R(\mathcal{P}[2]) &= (k-1)(a+b) + (k+1)(\gamma \text{rVP}a + b) \quad . \end{aligned}$$

Given the bound on ϵ , it is $\text{sc}_R(\mathcal{P}[1]) > \text{sc}_R(\mathcal{P}[2])$, thus $\text{Ideal}^1(\mathcal{P}_R)$ does not hold.

Second, we consider the case when N is odd: $\exists k \in \mathbb{N} : N = 2k + 1$.
Let $0 < \gamma < 1, 0 < \epsilon < \gamma \frac{1-rVP}{krVP}$,

$$\begin{aligned} \text{weakPost} &= \left(\underbrace{1, \dots, 1}_k, \underbrace{\gamma - \epsilon, \dots, \gamma - \epsilon}_k, \gamma \right) , \\ \text{strongPost} &= \left(\underbrace{\gamma, \dots, \gamma}_k, \underbrace{1, \dots, 1}_k, \gamma \right) , \\ \mathcal{P} &= \left[\text{weakPost}, \text{strongPost}, \underbrace{\text{nullPost}, \dots, \text{nullPost}}_{M-2} \right] . \end{aligned}$$

We first observe that

$$\begin{aligned} \forall j \in \{3, \dots, M\}, \text{idealSc}(\mathcal{P}[j]) &= 0 < \\ &< \text{idealSc}(\mathcal{P}[1]) = k + k(\gamma - \epsilon) + \gamma = \\ &= k + (k+1)\gamma - k\epsilon < k + (k+1)\gamma = \text{idealSc}(\mathcal{P}[2]) , \end{aligned}$$

thus the strong post has strictly the highest ideal score of all posts and as a result, $\forall \mathcal{P}'$ that contains the same posts as \mathcal{P} and $\text{IDEAL}^1(\mathcal{P}')$ holds, it is $\mathcal{P}'[1] = \mathcal{P}[2]$.

The first k and the last player vote first for $\mathcal{P}[1]$ and then for $\mathcal{P}[2]$, whereas players $k+1, \dots, 2k$ vote first for $\mathcal{P}[2]$ and then for $\mathcal{P}[1]$, thus at the end of the execution,

$$\begin{aligned} \text{sc}_R(\mathcal{P}[1]) &= k(a+b) + \gamma a + b + k((\gamma - \epsilon)rVPa + b) , \\ \text{sc}_R(\mathcal{P}[2]) &= k(a+b) + (k+1)(\gamma rVPa + b) . \end{aligned}$$

Given the bound on ϵ , it is $\text{sc}_R(\mathcal{P}[1]) > \text{sc}_R(\mathcal{P}[2])$, thus $\text{Ideal}^1(\mathcal{P}_R)$ does not hold.

Last but not least, we consider the case when $N = 2$. In this case, let $0 < \gamma < 1$ and

$$\mathcal{P} = \left[(1, 0), \left(\gamma, 1 - \gamma \frac{1+rVP}{2} \right), \underbrace{\text{nullPost}, \dots, \text{nullPost}}_{M-2} \right] .$$

It is $\forall j \in \{3, \dots, M\}, \text{idealSc}(\mathcal{P}[j]) = 0 < \text{idealSc}(\mathcal{P}[1]) = 1 \stackrel{rVP < 1}{<} 1 + \gamma \frac{1-rVP}{2} = \gamma + 1 - \gamma \frac{1+rVP}{2} = \text{idealSc}(\mathcal{P}[2])$, thus $\mathcal{P}[2]$ has strictly

the highest ideal score of all posts and as a result, $\forall \mathcal{P}'$ that contains the same posts as \mathcal{P} and $\text{IDEAL}^1(\mathcal{P}')$ holds, it is $\mathcal{P}'[1] = \mathcal{P}[2]$.

On the other hand, $\text{sc}_R(\mathcal{P}[1]) = a+2b > \gamma_{\text{rVP}}a+b+(1-\gamma_{\frac{1+\text{rVP}}{2}})a+b = \text{sc}_R(\mathcal{P}[2])$, thus $\text{Ideal}^1(\mathcal{P}_R)$ does not hold.
